**Abstract.** The paper presents a classical planning compilation for learning STRIPS action models from partial observations of plan executions. The compilation is flexible to different amounts and types of input knowledge, from learning samples that comprise partially observed intermediate states of the plan execution to samples in which only the initial and final states are observed. The compilation accepts also partially specified action models and it can be used to validate whether an observation of a plan execution follows a given STRIPS action model, even if the given model or the given observation are incomplete.

**Keywords:** Learning action models · Classical planning.

## 1 Introduction

Action models in planning are not only required for plan synthesis [9] but also for other tasks like plan/goal recognition [17, 18]. In both cases, automated planners are required to reason about action models that correctly and completely capture the possible world transitions [8]. Unfortunately building planning action models is complex, even for planning experts, and this knowledge acquisition task is a bottleneck that limits the potential of AI planning [13].

*Machine Learning* (ML) techniques have shown to be suitable to learn a wide range of different kinds of models from examples [16]. The application of inductive ML to learning STRIPS action models, the vanilla action model for planning [6], is not straightforward though:

- The input to ML algorithms (the learning/training data) is usually a finite vector that represents the value of some fixed object features. The input for learning planning action models is, however, the observation of plan executions, where each plan has a possibly different length (plan length is not a priori bounded) and refer to a different number of objects.
- The output of ML algorithms is usually a scalar value (an integer, in the case of classification tasks, or a real value, in the case of regression tasks). When learning action models the output is, for each action, the set of preconditions and effects that define the possible state transitions of a planning task.

Learning STRIPS action models is a well-studied problem with sophisticated algorithms such as ARMS [25], SLAF [2] or LOCM [4]. All of these learning systems are capable of dealing with partial or null observability of the intermediates states traversed along the plan execution but they also require a full specification of the sequence of actions of the learning examples. Motivated by recent advances on the synthesis of different kinds of generative models with classical planning [3, 20, 21, 22], this paper describes a classical planning compilation approach for learning STRIPS action models. The compilation approach is appealing by itself, because it opens up the door to the bootstrapping of planning action models, but also because it is flexible to different amounts and types of available input knowledge:

1. *Learning examples* can range from plans that comprise partially observed intermediate states of the plan execution to samples in which no intermediate state/action is observed, that is, only the initial and final states are observed.
2. *Partially specified action models*, expressing prior knowledge about the structure of actions, can also be provided to the compilation. In the extreme, the compilation can validate whether an observed plan execution is consistent with a given STRIPS action model, even if the model is not fully specified or the input observation is incomplete.

## 2 Background

In this section we formalize the *classical planning* model, for the *observation* model to represent the execution of a classical plan and the model for the *explanation of a given observation*.

### 2.1 Classical planning with conditional effects

$F$ is the set of *fluents* or *state variables* (propositional variables). A *literal* $l$ is a valuation of a fluent $f \in F$, i.e. either $l = f$ or $l = \neg f$. $L$ is a set of literals that represents a partial assignment of values to fluents, and $\mathcal{L}(F)$ is the set of all literals sets on $F$, i.e. all partial assignments of values to fluents. A *state* $s$ is a full assignment of values to fluents. We explicitly include negative literals $\neg f$ in states and so $|s| = |F|$ and the size of the state space is $2^{|F|}$.

A *planning frame* is a tuple $\Phi = \langle F, A \rangle$, where $F$ is a set of fluents and $A$ is a set of *actions*. An action $a \in A$ is defined with *preconditions*, $\mathsf{pre}(a) \in \mathcal{L}(F)$, and *effects* $\mathsf{eff}(a) \in \mathcal{L}(F)$. The semantics of actions $a \in A$ is specified with two functions: $\rho(s, a)$ denotes whether action $a$ is *applicable* in a state $s$ and $\theta(s, a)$ denotes the *successor state* that results of applying action $a$ in a state $s$. Therefore $\rho(s, a)$ holds iff $\mathsf{pre}(a) \subseteq s$ and the result of applying $a$ in $s$ is $\theta(s, a) = \{s \setminus \neg\mathsf{eff}(a)) \cup \mathsf{eff}(a)\}$, with $\neg\mathsf{eff}(a) = \{\neg l : l \in \mathsf{eff}(a)\}$.

A *planning problem* is defined as a tuple $P = \langle F, A, I, G \rangle$, where $I$ is the initial state in which all the fluents of $F$ are assigned a value true/false and $G$ is the goal set. A *plan* $\pi$ for $P$ is an action sequence $\pi = \langle a_1, \ldots, a_n \rangle$, and $|\pi| = n$

denotes its *plan length*. The execution of $\pi$ in the initial state $I$ of $P$ induces a *trajectory* $\tau = \langle s_0, a_1, s_1, \ldots, a_n, s_n \rangle$ such that $s_0 = I$ and, for each $1 \leq i \leq n$, it holds $\rho(s_{i-1}, a_i)$ and $s_i = \theta(s_{i-1}, a_i)$. A plan $\pi$ solves $P$ if $G$ holds in the last state of the induced trajectory $\tau$; i.e., $G \subseteq s_n$. A solution plan is *optimal* iff its length is minimal.

Now we define actions with *conditional effects* because they allow us to compactly define our compilation. An action $a_c \in A$ with conditional effects is defined as a set of preconditions $\mathsf{pre}(a_c) \in \mathcal{L}(F)$ and a set of *conditional effects* $\mathsf{cond}(a_c)$. Each conditional effect $C \rhd E \in \mathsf{cond}(a_c)$ is composed of two sets of literals: $C \in \mathcal{L}(F)$, the *condition*, and $E \in \mathcal{L}(F)$, the *effect*. An action $a_c \in A$ is applicable in a state $s$ if and only if $\mathsf{pre}(a_c) \subseteq s$, and the *triggered effects* resulting from the action application are the effects whose conditions hold in $s$:

$$triggered(s, a_c) = \bigcup_{C \rhd E \in \mathsf{cond}(a_c), C \subseteq s} E.$$

The result of applying $a_c$ in state $s$ follows the same definition of successor state, $\theta(s, a)$, but applied to the conditional effects in $triggered(s, a_c)$.

### 2.2 The observation model

Given a planning problem $P = \langle F, A, I, G \rangle$, a plan $\pi$ that solves $P$, and the corresponding trajectory $\tau$ induced by the execution of $\pi$ in $I$, $\tau = \langle s_0, a_1, s_1, \ldots, a_n, s_n \rangle$; there exist as many observations of $\tau$ as combinations of observable actions and observable fluents of the states of $\tau$. *The observation model of the trajectory* $\tau$ comprises all possible combinations of observable elements of $\tau$. We will refer to the set of observations of $\tau$ as $Obs(\tau)$.

Formally, one observation in $Obs(\tau)$ is defined as $\mathcal{O} = \langle s_0^o, s_1^o \ldots, s_m^o \rangle$, $s_0^o = I$, a sequence of possibly *partially observable states*, except for the initial state $s_0^o$ which is fully observable. A partially observable state is one in which $|s_i^o| < |F|$, $1 \leq i \leq m \leq n$; i.e., a state in which at least a fluent of $F$ is not observable. It may be also the case that $|s_i^o| = 0$ when an intermediate state is fully unobservable. The *minimal observation* needed by our model is $\mathcal{O} = \langle s_0^o, s_1^o \rangle$, where $s_0^0$ is the fully observable initial state and $s_1^o$ is a partially observable final state.

The observation model can also include *observed actions* as fluents indicating the applied action in a given state. This means that a sequence of observed actions $\langle a_1^o, \ldots, a_l^o \rangle$ is a sub-sequence of $\pi = \langle a_1, \ldots, a_n \rangle$ such that $a_i^o \in s_{i-1}^o$, $0 \leq i \leq l$. Consequently, the number of fluents that represent observed actions, $l$, can range from 0 (in a fully unobservable action sequence) to $|\pi| = n$ (in a fully observed action sequence).

Given $\mathcal{O} \in Obs(\tau)$, the number of observed states of $\mathcal{O} = \langle s_0^o, s_1^o \ldots, s_m^o \rangle$ ranges from 2 (at least the initial and final state, as explained above) to $|\pi| + 1$. The number of fluents of the full observable state $s_0^o$ will be $|F|$, or $|F| + 1$ in case the fluent of the applied action in $s_0$ is also observed. Every observable intermediate state will comprise a number of fluents between $[1, |F| + 1]$, where a single fluent may represent a sensing fluent of the state or the observation of the applied action.

This observation model can also distinguish between *observable state variables*, whose value may be read from sensors, and *hidden* (or *latent*) *state variables*, that cannot be observed. Given a subset of fluents $\Gamma \subseteq F$ we say that $\mathcal{O}$ is a $\Gamma$-observation of the execution of $\pi$ on $P$ iff for every observed state $s^o_i$, $1 \leq i \leq m$, $s^o_i$ only contains fluents in $\Gamma$.

### 2.3 Explaining observations with classical planning

In this section we will explore the relationship between a trajectory $\tau$ and an observation $\mathcal{O}$. Particularly, we are interested in determining the necessary conditions for $\mathcal{O}$ to belong to $Obs(\tau)$. When the membership $\mathcal{O} \in Obs(\tau)$ is established, we say that $\mathcal{O}$ is *consistent* with $\tau$ or that $\tau$ *explains* $\mathcal{O}$.

For the sake of simplicity, and given that our observation model encodes the observed applicable actions as fluents in the corresponding state, we will denote a trajectory as $\tau = \langle s'_0, s'_1, \ldots, s'_n \rangle$, where $s'_i$ comprises a fluent representing the applicable action $a_{i+1}$ in $s'_i$.

Given an observation $\mathcal{O} = \langle s^o_0, s^o_1 \ldots, s^o_m \rangle$ and a trajectory $\tau = \langle s'_0, s'_1, \ldots, s'_n \rangle$, where $m \leq n$, $s^o_0 = s'_0$ and $s^o_m \subseteq s'_n$, it holds that $\mathcal{O} \in Obs(\tau)$ iff $\tau$ embeds $\mathcal{O}$; i.e., if there is a monotonic function $f$ mapping the observation indices $j = 1, 2, \ldots, m$ into the trajectory indices $i = 1, 2, \ldots, n$ such that $s^o_j \subseteq s'_{f(j)}$. This definition is a generalization of the one introduced in [17], which states the conditions under which an action sequence satisfies an observation sequence. Since all the elements (sets) of $\mathcal{O}$ are associated to an element (set) of $\tau$, but not viceversa, the fluents of a set of $\mathcal{O}$ are all included in the corresponding set of $\tau$, we can say that $\tau$ is a superset of $\mathcal{O}$. All this means that transiting between two consecutive observed states in $\mathcal{O}$ may require the execution of more than a single action $(\theta(s^o_i, \langle a_1, \ldots, a_k \rangle) = s^o_{i+1}$, where $k \geq 1$ is unknown but finite. In other words, the information of $\mathcal{O}$ does not imply knowing the actual length of the trajectory $\tau$.

Given a planning frame $\Phi = \langle F, A \rangle$ and an observation of a plan execution, $\mathcal{O} = \langle s^o_0, s^o_1 \ldots, s^o_m \rangle$, we define $P_{\mathcal{O}}$, within the given planning frame, as the planning problem that is built as follows: $P_{\mathcal{O}} = \langle F, A, s^o_0, s^o_m \rangle$.

**Definition 1 (Explanation).** *A plan $\pi$ (or the trajectory $\tau$) **explains** $\mathcal{O}$ iff $\pi$ is a solution for $P_{\mathcal{O}}$ and $\mathcal{O} \in Obs(\tau)$.*

There may exist more than one solution plan for $P_{\mathcal{O}}$, one or more of which will be optimal solutions if their plan length is minimal. Additionally, other solutions longer than the optimal plan can also be found.

**Definition 2 (Best explanation).** *A plan $\pi$ (or the trajectory $\tau$) that solves $P_{\mathcal{O}}$ is the **best explanation** for $\mathcal{O}$ iff $|\pi| = n$ and for every other $\tau_i$ s.t. $\mathcal{O} \in Obs(\tau_i)$, $|\pi_i| > n$.*

That is, in case that $\pi$ is optimal, we say that $\pi$ is the **best explanation** for the input observation $\mathcal{O}$.

The observation $\mathcal{O}$ can also be regarded as a sequence of ordered *landmarks* for the planning problem $P_{\mathcal{O}}$ [10] since all the fluents of the sets in $\mathcal{O}$ must be achieved by any plan that solves $P_{\mathcal{O}}$ and in the same order as defined in the observation $\mathcal{O}$.

## 3 Explanation-based learning of Strips action models

The task of learning action models by explaining the observation of a plan execution is defined as a tuple $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$, where:

- $\mathcal{M}$ is the *initial empty model* that contains only the *header* (i.e., the *name* and *parameters*) of each action model to be learned.
- $\mathcal{O} = \langle s_0^o, s_1^o \ldots, s_m^o \rangle$ is a sequence of partially observed states, except for the initial state $s_0^o$ which is fully observable.

A *solution* to a $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$ learning task is a model $\mathcal{M}'$ that is consistent with the headers of $\mathcal{M}$ and that explains $\mathcal{O}$. We say that a model $\mathcal{M}'$ explains an observation $\mathcal{O}$ iff there exists a solution plan for $P_{\mathcal{O}} = \langle F, A, s_0^o, s_m^o \rangle$, where the semantics of the set of actions $A$ are given by $\mathcal{M}'$, such that $\pi$ explains $\mathcal{O}$. The set of fluents $F \in P_{\mathcal{O}}$ is induced from $s_0^o \in \mathcal{O}$ since it represents a full state.

### 3.1 The space of Strips action models

We analyze here the solution space of the addressed learning task; in this case the space of Strips action models.

A Strips *action model* is defined as $\xi = \langle name(\xi), pars(\xi), pre(\xi), add(\xi), del(\xi) \rangle$, where $name(\xi)$ and parameters, $pars(\xi)$, define the header of $\xi$; and $pre(\xi)$, $del(\xi)$ and $add(\xi)$) are sets of fluents that represent the *preconditions*, *negative effects* and *positive effects*, respectively, of the actions induced from the action model $\xi$.

Let $\Psi$ be the set of *predicates* that shape the fluents $F$ (the initial state of an observation is a full assignment of values to fluents, $|s_0^o| = |F|$, and so the predicates $\Psi$ are extractable from the observed state $s_0^o$). The set of propositions that can appear in $pre(\xi)$, $del(\xi)$ and $add(\xi)$ of a given $\xi$, denoted as $\mathcal{I}_{\xi,\Psi}$, are FOL interpretations of $\Psi$ over the parameters $pars(\xi)$. For instance, in a four-operator *blocksworld* [23], the $\mathcal{I}_{\xi,\Psi}$ set contains five elements for the `pickup(`$v_1$`)` model, $\mathcal{I}_{pickup,\Psi}$=`{handempty, holding(`$v_1$`),clear(`$v_1$`),ontable(`$v_1$`), on(`$v_1, v_1$`)}` and eleven elements for the model of `stack(`$v_1$`,`$v_2$`)`, $\mathcal{I}_{stack,\Psi}$=`{handempty, holding(`$v_1$`), holding(`$v_2$`), clear(`$v_1$`),clear(`$v_2$`),ontable(`$v_1$`),ontable(`$v_2$`), on(`$v_1, v_1$`),on(`$v_1, v_2$`), on(`$v_2, v_1$`), on(`$v_2, v_2$`)}`. Hence, solving a $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$ learning task is determining which elements of $\mathcal{I}_{\xi,\Psi}$ will shape the preconditions, positive and negative effects of the corresponding action model.

In principle, for a given Strips action model $\xi$, any element of $\mathcal{I}_{\xi,\Psi}$ can potentially appear in $pre(\xi)$, $del(\xi)$ and $add(\xi)$. In practice, the actual space of possible Strips schemata is bounded by:

1. **Syntactic constraints**. The solution $\mathcal{M}'$ must be consistent with the STRIPS constraints: $del(\xi) \subseteq pre(\xi)$, $del(\xi) \cap add(\xi) = \emptyset$ and $pre(\xi) \cap add(\xi) = \emptyset$. *Typing constraints* are also a type of syntactic constraint that reduce the size of $\mathcal{I}_{\xi,\Psi}$ [15].
2. **Observation constraints**. The solution $\mathcal{M}'$ must be consistent with these *semantic constraints* derived from the input observation $\mathcal{O}$. Specifically, the states induced by plans computable with $\mathcal{M}'$ must comprise the observed states of the sample, which further constrains the space of possible action models.

Considering only the syntactic constraints, the size of the space of possible STRIPS models is given by $2^{2\times|\mathcal{I}_{\Psi,\xi}|}$ because one element in $\mathcal{I}_{\xi,\Psi}$ can appear both in the preconditions and effects of $\xi$. Given $p \in \mathcal{I}_{\Psi,\xi}$, the belonging of $p$ to the preconditions, positive effects or negative effects of $\xi$ is handled with a propositional encoding that uses fluents of two types, $pre_{p,\xi}$ and $eff_{p,\xi}$. The four possible combinations of these two fluents are summarized in Figure 1. This compact encoding allows for a more effective exploitation of the syntactic constraints, and also yields the solution space of $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$ to be the same as its search space.

| **Encoding** | **Meaning** |
|---|---|
| $\neg pre_{p,\xi} \wedge \neg eff_{p,\xi}$ | $p$ belongs neither to the preconditions nor effects of $\xi$ ($p \notin pre(\xi) \wedge p \notin add(\xi) \wedge p \notin del(\xi)$) |
| $pre_{p,\xi} \wedge \neg eff_{p,\xi}$ | $p$ is only a precondition of $\xi$ ($p \in pre(\xi) \wedge p \notin add(\xi) \wedge p \notin del(\xi)$) |
| $\neg pre_{p,\xi} \wedge eff_{p,\xi}$ | $p$ is a positive effect of $\xi$ ($p \notin pre(\xi) \wedge p \in add(\xi) \wedge p \notin del(\xi)$) |
| $pre_{p,\xi} \wedge eff_{p,\xi}$ | $p$ is a negative effect of $\xi$ ($p \in pre(\xi) \wedge p \notin add(\xi) \wedge p \in del(\xi)$) |

**Fig. 1.** Combinations of the propositional encoding and their meaning

To illustrate better this encoding, Figure 2 shows the PDDL encoding of the `stack(?v1,?v2)` schema and our propositional representation for this same schema with $pre_{p,stack}$ and $eff_{p,stack}$ fluents ($p \in \mathcal{I}_{\Psi,stack}$).

### 3.2 The sampling space

According to our *observation model* the minimal expression of an observation must comprise at least two state observations $\mathcal{O} = \langle s_0^o, s_m^o \rangle$, a fully observable initial state $s_0^o$ and a partially observed final state $s_m^o$. Figure 3 shows an example of $\mathcal{O} = \langle s_0^o, s_m^o \rangle$ observation that contains only two states. An initial state of the blocksworld where the robot hand is empty and there are two blocks (`blockB` on

```

(eff_clear_v1_stack) (eff_handempty_stack) (eff_on_v1_v2_stack)
```

**Fig. 2.** PDDL encoding of the `stack(?v1,?v2)` schema and our propositional representation for this same schema.

top of `blockA`). The observation represents also a partially observable final state in which `blockA` is on top of `blockB`.

On the other hand, the maximal expression of an observation corresponds to a fully observed trajectory $\mathcal{O} = \tau$, meaning that all traversed states, and applied actions, are fully observed. Between our minimal and maximal expressions of observation, there exists a whole range of possible degrees of observability. For example, the majority of learning systems such as ARMS [25] or SLAF [2] use observations that comprise the initial state and all the actions of the executed plan.

## 4 Learning Strips action models with classical planning

Our approach to address a learning task $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$ is to compile it into a classical planning problem $P_\Lambda$. The intuition behind the compilation is that when $P_\Lambda$ is solved, the solution plan $\pi_\Lambda$ is a sequence of actions that build the output model $\mathcal{M}'$ and verify that $\mathcal{M}'$ is consistent with the observation $\mathcal{O}$.

A solution plan $\pi_\Lambda$ comprise then two differentiated blocks of actions: a plan prefix with a set of actions each defining the **insertion** of a fluent as a *precondition* or a *effect* of an action model; and a plan postfix with a set of actions that determine the **application** of the learned modes while successively **validating** the effects of the action application in every partial state in $\mathcal{O}$. Roughly speaking, in the *blocksworld*, the format of the first set of actions of $\pi_\Lambda$ looks like `(insert_pre_stack_holding_v1), (insert_eff_stack_clear_v1), (insert_eff_stack_holding_v1)`... where the first effect denotes a positive effect and the second one a negative effect to be inserted in $name(\xi)$ =`stack`; and the format of the second set of actions of $\pi_\Lambda$ is like `(apply_unstack blockB blockA),(apply_putdown blockB)` and `(validate_1), (validate_2)`, where the last two actions denote the points at which the states generated through the action application must be validated with the observed states in $\mathcal{O}$.

### 4.1 Compilation

Given a learning task $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$ the compilation outputs a classical planning task $P_\Lambda = \langle F_\Lambda, A_\Lambda, I_\Lambda, G_\Lambda \rangle$ such that:

- $F_\Lambda$ extends the set of fluents $F$ (obtained from $s_0^o$) with the model fluents to represent the preconditions and effects of each $\xi \in \mathcal{M}$ as well as some other fluents to keep track of the validation of $\mathcal{O}$. Specifically, $F_\Lambda$ contains also:
  - Fluents $pre_{p,\xi}$ and $eff_{p,\xi}$, defined as explained in section 3.1.
  - A set of fluents $\{test_j\}_{0 \leq j \leq m}$, to point at the state observation $s_j^o \in \mathcal{O}$ where the action model is validated. In the example of Figure 3 two tests are required to validate the programmed action model, one corresponding to the initial state and the second one corresponding to the final state.
  - A fluent, $mode_{prog}$, to indicate whether action models are being programmed or validated and a fluent *invalid* to indicate that the programmed action model is inconsistent with the input observation.
- $I_\Lambda$ encodes $s_0^o$ and the following fluents set to true: $mode_{prog}$, $test_0$. Our compilation assumes that action models are initially programmed with no precondition, no negative effect and no positive effect.
- $G_\Lambda$ includes the positive literal $test_m$ and the negative literal $\neg invalid$. When these goals are achieved by the solution plan $\pi_\Lambda$, we will be certain that the action models of $\mathcal{M}'$ are validated in the input observation.
- $A_\Lambda$ includes three types of actions that give rise to the actions of $\pi_\Lambda$.
  1. Actions for *inserting* a precondition or effect into $\xi \in \mathcal{M}$ following the syntactic constraints of STRIPS models. These actions will form the prefix of the solution plan $\pi_\Lambda$. Among the *inserting* actions, we find:
     - Actions for inserting a *precondition* $p \in \mathcal{I}_{\xi,\Psi}$ into $\xi$.

$$\mathsf{pre}(\mathsf{insertPre}_{\mathsf{p},\xi}) = \{\neg pre_{p,\xi}, \neg eff_{p,\xi}, mode_{prog}\},$$
$$\mathsf{cond}(\mathsf{insertPre}_{\mathsf{p},\xi}) = \{\emptyset\} \rhd \{pre_{p,\xi}\}.$$

- Actions for inserting a *effect* $p \in \mathcal{I}_{\xi,\Psi}$ into $\xi$.

$$\begin{aligned}\mathsf{pre}(\mathsf{insertEff}_{\mathsf{p},\xi}) =& \{\neg eff_{p,\xi}, mode_{prog}\},\\ \mathsf{cond}(\mathsf{insertEff}_{\mathsf{p},\xi}) =& \{\emptyset\} \rhd \{eff_{p,\xi}\}\end{aligned}$$

For instance, given $name(\xi) =$`stack` and {`(pre_stack_holding_v1)`, `(pre_stack_holding_v2)`, `(pre_stack_on_v1_v2)`, `(pre_stack_clear_v1)`, `(pre_stack_clear_v1)`, ...}, the insertion of each item $p \in \mathcal{I}_{\xi,\Psi}$ in $\xi$ will generate a different alternative in the search space when solving $P_\Lambda$. The same applies to effects {`(eff_stack_holding_v1)`, `(eff_stack_holding_v2)`, `(eff_stack_on_v1_v2)`, `(eff_stack_clear_v1)`, `(eff_stack_clear_v1)`,...}.

Note that executing an insert action, e.g.`(insert_pre_stack_holding_v1)`, will add the corresponding model fluent `(pre_stack_holding_v1)` to the successor state. Hence, the execution of the insert actions of $\pi_\Lambda$ yield a state containing the valuation of the model fluents that shape every $\xi \in \mathcal{M}$. For example, executing the insert actions that shape the action model $name(\xi) =$`putdown` leads to a state containing the positive literals `(pre_putdown_holding_v1)`,`(eff_putdown_holding_v1)`, `(eff_putdown_clear_v1)`, `(eff_putdown_ontable_v1)`,`(eff_putdown_handempty)`.

2. Actions for *applying* the action models $\xi \in \mathcal{M}$ built by the insert actions and bounded to objects $\omega \subseteq \Omega^{ar(\xi)}$. These actions will be part of the postfix of the plan $\pi_\Lambda$ and they determine the application of the learned action models according to the values of the model fluents in the current state configuration. Since action headers are known, the variables $pars(\xi)$ are bounded to the objects in $\omega$ that appear in the same position.

$$\begin{aligned}\mathsf{pre}(\mathsf{apply}_{\xi,\omega}) =& \{\},\\ \mathsf{cond}(\mathsf{apply}_{\xi,\omega}) =& \{pre_{p,\xi} \wedge eff_{p,\xi}\} \rhd \{\neg p(\omega)\}_{\forall p \in \Psi_\xi},\\ & \{\neg pre_{p,\xi} \wedge eff_{p,\xi}\} \rhd \{p(\omega)\}_{\forall p \in \Psi\xi},\\ & \{pre_{p,\xi} \wedge \neg p(\omega)\}_{\forall p \in \Psi_\xi} \rhd \{invalid\},\\ & \{mode_{prog}\} \rhd \{\neg mode_{prog}\}.\end{aligned}$$

Figure 4 shows the PDDL encoding of `(apply_stack)` for applying the action model of the *stack* operator. Let's assume the action `(apply_stack blockB blockA)` is in $\pi_\Lambda$. Executing this action in a state $s$ implies activating the preconditions and effects of `(apply_stack)` according to the values of the model fluents in $s$. For example, if {`(pre_stack_holding_v1)`,`(pre_stack_clear_v2)`} $\subset$ $s$ then it must be checked that positive literals `(holding blockB)` and `(clear blockA)` hold in $s$. Otherwise, a different set of precondition literals will be checked. The same applies to the conditional effects, generating the corresponding literals according to the values of the model fluents of $s$.

Note that executing an apply action, e.g.`(apply_stack blockB blockA)`, will add the literals `(on blockB blockA)`,`(clear blockB)`,`(not(clear blockA))`,`(handempty)`

and `(not(clear blockB))` to the successor state if $name(\xi) =$`stack` has been correctly programmed by the insert actions. Hence, while **insert actions** add the values of the **model fluents** that shape $\xi$, the **apply actions** add the values of the **fluents of** $F$ that result from the execution of $\xi$.

```
(:action apply_stack
  :parameters (?o1 - object ?o2 - object)
  :precondition (and )

```

**Fig. 4.** PDDL action for applying an already programmed model for *stack*.

When the input plan trace contains observed actions extra preconditions have to be added to ensure that actions are applied in the same order as they appear in $\mathcal{O}$ [1].

3. Actions for *validating* partially observed states $s^o_j \in \mathcal{O}$. These actions are also part of the postfix of the solution plan $\pi_\Lambda$ and they are aimed at checking that the observation $\mathcal{O}$ follows after the execution of the apply actions.

$$\begin{aligned}\mathsf{pre}(\mathsf{validate_j}) =& s_j^o \cup \{test_{j-1}\},\\ \mathsf{cond}(\mathsf{validate_j}) =& \{\emptyset\} \rhd \{\neg test_{j-1}, test_j\}.\end{aligned}$$

There will be a validate action in $\pi_\Lambda$ for every observed state in $\mathcal{O}$. The position of the validate actions in $\pi_\Lambda$ will be determined by the planner by checking that the state resulting after the execution of an apply action comprises the observed state $s_j^o \in \mathcal{O}$.

In some contexts, it is reasonable to assume that some parts of the action model are known and so there is no need to learn the entire model from scratch [26]. In our compilation approach, when an action model $\xi$ is partially specified, the known preconditions and effects are encoded as fluents $pre_{p,\xi}$ and $eff_{p,\xi}$ set to true in the initial state $I_\Lambda$. In this case, the corresponding insert actions, $\mathsf{insertPre_{p,\xi}}$ and $\mathsf{insertEff_{p,\xi}}$, become unnecessary making the classical planning task $P_\Lambda$ easier to be solved.

So far we explained the compilation for learning from a single input trace. However, the compilation is extensible to the more general case $\Lambda = \langle \mathcal{M}, \mathcal{O}_1, \ldots, \mathcal{O}_k \rangle$ where there is an input set of $k$ observations. Taking this into account, a small modification is required in our compilation approach. In particular, the actions in $P_\Lambda$ for *validating* the last state $s_{m,t}^o \in \mathcal{O}_t$, $1 \leq t \leq k$ of an observation $\mathcal{O}_t$ reset the current state. These actions are now redefined as:

$$\begin{aligned}\mathsf{pre}(\mathsf{validate_j}) =& s_{m,t}^o \cup \{test_{j-1}\} \cup \{\neg mode_{prog}\},\\ \mathsf{cond}(\mathsf{validate_j}) =& \{\emptyset\} \rhd \{\neg test_{j-1}, test_j\} \cup\\ & \{\neg f\}_{\forall f \in s_{m,t}^o, f \notin s_{0,t+1}^o} \cup \{f\}_{\forall f \in s_{0,t+1}^o, f \notin s_{m,t}^o}.\end{aligned}$$

Finally, we will detail the composition of a solution plan $\pi_\Lambda$ to a planning task $P_\Lambda$ and the mechanism to extract the action models of $\mathcal{M}'$ from $\pi_\Lambda$. The plan of Figure 5 shows a solution to the task $P_\Lambda$ that encodes a learning task $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$ for obtaining the action models of the *blocksworld* domain, where the models for `pickup`, `putdown` and `unstack` are already specified in $\mathcal{M}$. Therefore, the plan shows the insert actions and validate action for the action model `stack`. Plan steps $00 - 01$ insert the preconditions of the `stack` model, steps $02 - 06$ insert the action model effects, and steps $07 - 11$ form the plan postfix that applies the action models (only the `stack` model is learned) and validates the result in the input observation.

Given a solution plan $\pi_\Lambda$ that solves $P_\Lambda$, the set of action models $\mathcal{M}'$ that solves $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$ learning task are computed in linear time and space. In order to do so, $\pi_\Lambda$ is executed in the initial state $I_\Lambda$ and the action model $\mathcal{M}'$ will be given by the fluents $pre_{p,\xi}$, and $eff_{p,\xi}$ that are set to true in the last state reached by $\pi_\Lambda$, $s_g = \theta(I_\Lambda, \pi_\Lambda)$. For each $\xi \in \mathcal{M}'$, we build the sets of preconditions, positive effects and negative effects as follows:

```
00 : (insert_pre_stack_holding_v1)
01 : (insert_pre_stack_clear_v2)
02 : (insert_eff_stack_clear_v1)
03 : (insert_eff_stack_clear_v2)
04 : (insert_eff_stack_handempty)
05 : (insert_eff_stack_holding_v1)
06 : (insert_eff_stack_on_v1_v2)
07 : (apply_unstack blockB blockA i1 i2)
08 : (apply_putdown blockB i2 i3)
09 : (apply_pickup blockA i3 i4)
10 : (apply_stack blockA blockB i4 i5)
11 : (validate_1)
```

**Fig. 5.** Plan for programming the *stack* action model and for validating the programmed *stack* action model with previously specified action models for *pickup*, *putdown* and *unstack*.

$$
\begin{aligned}
pre(\xi) =& \{p \mid pre_{p,\xi} \in s_g\}_{\forall p \in \Psi_\xi}, \\
del(\xi) =& \{p \mid pre_{p,\xi} \wedge eff_{p,\xi} \in s_g\}_{\forall p \in \Psi_\xi}, \\
add(\xi) =& \{p \mid \neg pre_{p,\xi} \wedge eff_{p,\xi} \in s_g\}_{\forall p \in \Psi_\xi}.
\end{aligned}
$$

The plain compilation has trouble learning preconditions that do not appear as negative effects since in this case no change can be observed between the *pre-state* and *post-state* of an action application. This is specially relevant for static predicates that never change and, hence, only appear as preconditions in the actions. To address this shortcoming and complete the list of learned preconditions, we apply a post-process based on the one proposed by the LOUGA system [14]. The intuition is going through every action counting the number of cases where a literal is present before the action is executed. If a literal is present in all the cases before the action, the literal is considered to be a precondition. Since intermediate states/actions may not be fully observed in a observation $\mathcal{O}$, we consider the actions/states found in the validation part of the solution plan $\pi_\Lambda$. For instance, in the example of Figure 5, the used sequence of actions is `(unstack blockB blockA)`, `(put-down blockB)`, `(pick-up blockA)`, and `(stack blockA blockB)`.

### 4.2 Properties of the compilation

**Lemma 1** *Soundness. Any classical plan $\pi$ that solves $P_\Lambda$ produces a model $\mathcal{M}'$ that solves the $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$ learning task.*

*Proof ().* According to the $P_\Lambda$ compilation, once a given precondition or effect is inserted into the domain model $\mathcal{M}$ it cannot be undone. In addition, once an action model is applied it cannot be modified. In the compiled planning problem $P_\Lambda$, only

$(\texttt{apply})_{\xi,\omega}$ actions can update the value of the state fluents $F$. This means that a state consistent with an observation $s^o_m$ can only be achieved executing an applicable sequence of $(\texttt{apply})_{\xi,\omega}$ actions that, starting in the corresponding initial state $s^o_0$, validates that every generated intermediate state $s_j$ $(0 < j \leq m)$, is consistent with the input state observations. This is exactly the definition of the solution condition for model $\mathcal{M}'$ to solve the $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$ learning task.

**Lemma 2** *Completeness. Any model $\mathcal{M}'$ that solves the $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$ learning task can be computed with a classical plan $\pi$ that solves $P_\Lambda$.*

*Proof ().* By definition $\mathcal{I}_{\xi,\Psi}$ fully captures the set of elements that can appear in an action model $\xi$ using predicates $\Psi$. In addition the $P_\Lambda$ compilation does not discard any model $\mathcal{M}'$ definable within $\mathcal{I}_{\xi,\Psi}$. This means that, for every model $\mathcal{M}'$ that solves the $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$, we can build a plan $\pi$ that solves $P_\Lambda$ by selecting the appropriate $(\texttt{insert\_pre})_{\texttt{p},,\xi}$ and $(\texttt{insert\_eff})_{\texttt{p},\xi}$ actions for programming the precondition and effects of the corresponding action models in $\mathcal{M}'$ and then, selecting the corresponding $(\texttt{apply})_{\xi,\omega}$ actions that transform the initial state observation $s^o_0$ into the final state observation $s^o_m$.

The size of the classical planning problem $P_\Lambda$ depends on the arity of the predicates in $\Psi$, that shape variables $F$, and the number of parameters of the action models, $|pars(\xi)|$. The larger these arities, the larger $|\mathcal{I}_{\xi,\Psi}|$. The size of $\mathcal{I}_{\xi,\Psi}$ is the most dominant factor of the compilation because it defines the $pre_{p,\xi}/eff_{p,\xi}$ fluents, the corresponding set of `insert` actions, and the number of conditional effects in the $(\texttt{apply})_{\xi,\omega}$ actions. Note that *typing* can be used straightforward to constrain the FOL interpretations of $\Psi$ over the parameters $pars(\xi)$, which will significantly reduce $|\mathcal{I}_{\xi,\Psi}|$ and hence the size of $P_\Lambda$ output by the compilation.

Classical planners tend to prefer shorter solution plans, so our compilation may introduce a bias to $\Lambda = \langle \mathcal{M}, \mathcal{O} \rangle$ learning tasks preferring solutions that are referred to action models with a shorter number of preconditions/effects. In more detail, all $\{pre_{p,\xi}, eff_{p,\xi}\}_{\forall e \in \mathcal{I}_{\xi,\Psi}}$ fluents are false at the initial state of our $P_\Lambda$ compilation so classical planners tend to solve $P_\Lambda$ with plans that require a smaller number of `insert` actions.

This bias can be eliminated defining a cost function for the actions in $P_\Lambda$ (e.g. `insert` actions have *zero cost* while $(\texttt{apply})_{\xi,\omega}$ actions have a *positive constant cost*). In practice we use a different approach to disregard the cost of `insert` actions since classical planners are not proficient at optimizing plan cost with zero-cost actions. Instead, our approach is to use a SAT-based planner [19] that can apply all actions for inserting preconditions in a single planning step (these actions do not interact). Further, the actions for inserting action effects are also applied in another single planning step. The plan horizon for programming any action model is then always bounded to 2. The SAT-based planning approach is also convenient for its ability to deal with planning problems populated with dead-ends and because symmetries in the insertion of preconditions/effects into an action model do not affect the planning performance.

An interesting aspect of our approach is that when a *fully* or *partially specified* STRIPS action model $\mathcal{M}$ is given in $\Lambda$, the $P_\Lambda$ compilation also serves to validate whether the observation $\mathcal{O}$ follows the given model $\mathcal{M}$:

- $\mathcal{M}$ is proved to be a *valid* action model for the given input data $\mathcal{O}$ iff a solution plan for $P_\Lambda$ can be found.
- $\mathcal{M}$ is proved to be a *invalid* action model for the given input data $\mathcal{O}$ iff $P_\Lambda$ is unsolvable. This means that $\mathcal{M}$ cannot be consistent with the given observation of the plan execution.

This validation capacity of our compilation is beyond the functionality of VAL (the plan validation tool [11]) because our $P_\Lambda$ compilation is able to address *model validation* of a partial (or even an empty) action model with a partially observed plan trace. VAL, however, requires a full plan and a full action model for plan validation.

## 5 Experimental results

## 6 Conclusions

We presented a classical planning compilation for learning STRIPS action models from partial observations of plan executions. To the best of our knowledge, this is the first approach on learning action models that is exhaustively evaluated over a wide range of domains and uses exclusively an *off-the-shelf* classical planner. The work in [24] proposes a planning compilation for learning action models from plan traces following the *finite domain* representation for the state variables. This is a theoretical study on the boundaries of the learned models and no experimental results are reported.

When example plans are available, we can compute accurate action models from small sets of learning examples (five examples per domain) in little computation time (less than a second). When action plans are not available, our approach still produces action models that are compliant with the input information. In this case, since learning is not constrained by actions, operators can be reformulated changing their semantics, in which case the comparison with a reference model turns out to be tricky.

An interesting research direction related to this issue is *domain reformulation* to use actions in a more efficient way, reduce the set of actions identifying dispensable information or exploiting features that allow more compact solutions like the *reachable* or *movable* features in the *Sokoban* domain [12].

Generating *informative* examples for learning planning action models is still an open issue. Planning actions include preconditions that are only satisfied by specific sequences of actions which have low probability of being chosen by chance [5]. The success of recent algorithms for exploring planning tasks [7] motivates the development of novel techniques that enable to autonomously collect informative learning examples. The combination of such exploration techniques with our learning approach is an appealing research direction that opens up the door to the bootstrapping of planning action models.
