Abstract

1 Introduction

Given an input sequence of partially observed states, this paper formalizes the task of computing the *least-commitment* action model that is able to *explain* the given observation. This task is of interest because it allows the incremental learning of action models from arbitrary large sets of partial observations.

In addition, the paper introduces a new method to compute the *least-commitment* action model for an input sequence of partially observed states. The method assumes that action models are specified as STRIPS action schemata and it is built on top of off-the-shelf algorithms for *classical planning*.

2 Background

This section formalizes the *planning models* we use in the paper as well as the kind of state *observations* that are given as input for computing the *least-commitment* action model.

2.1 Classical planning with conditional effects

Let F be the set of *fluents* or *state variables* (propositional variables) describing a state. A *literal* l is a valuation of a fluent $f \in F$; i.e. either $l = f$ or $l = \neg f$. A set of literals L represents a partial assignment of values to fluents (without loss of generality, we will assume that L does not contain conflicting values). Given L , let $\neg L = \{\neg l : l \in L\}$ be its complement. We use $\mathcal{L}(F)$ to denote the set of all literal sets on F ; i.e. all partial assignments of values to fluents. A *state* s is a full assignment of values to fluents; $|s| = |F|$.

A *classical planning frame* is a tuple $\Phi = \langle F, A \rangle$, where F is a set of fluents and A is a set of *actions*. Each classical planning action $a \in A$ has a precondition $\text{pre}(a) \in \mathcal{L}(F)$ and a set of effects $\text{eff}(a) \in \mathcal{L}(F)$. The semantics of actions $a \in A$ is specified with two functions: $\rho(s, a)$ denotes whether action a is *applicable* in a state s and $\theta(s, a)$ denotes the *successor state* that results of applying action a in a state s . Then, $\rho(s, a)$ holds iff $\text{pre}(a) \subseteq s$, i.e. if its precondition holds in s . The result of executing an applicable action $a \in A$ in a state s is a new state $\theta(s, a) = (s \setminus \neg \text{eff}(a)) \cup \text{eff}(a)$. Subtracting the complement of $\text{eff}(a)$ from s ensures that $\theta(s, a)$

remains a well-defined state. The subset of action effects that assign a positive value to a state fluent is called *positive effects* and denoted by $\text{eff}^+(a) \in \text{eff}(a)$ while $\text{eff}^-(a) \in \text{eff}(a)$ denotes the *negative effects* of an action $a \in A$.

A *classical planning problem* is a tuple $P = \langle F, A, I, G \rangle$, where I is the initial state and $G \in \mathcal{L}(F)$ is the set of goal conditions over the state variables. A *plan* π is an action sequence $\pi = \langle a_1, \dots, a_n \rangle$, with $|\pi| = n$ denoting its *plan length*. The execution of π on the initial state I of P induces a *trajectory* $\tau(\pi, s_0) = \langle s_0, a_1, s_1, \dots, a_n, s_n \rangle$ such that $s_0 = I$ and, for each $1 \leq i \leq n$, it holds $\rho(s_{i-1}, a_i)$ and $s_i = \theta(s_{i-1}, a_i)$. A plan π solves P iff the induced *trajectory* $\tau(\pi, s_0)$ reaches a final state $G \subseteq s_n$, where all goal conditions are met. A solution plan is optimal iff its length is minimal.

An action $a_c \in A$ with conditional effects is defined as a set of preconditions $\text{pre}(a_c) \in \mathcal{L}(F)$ and a set of *conditional effects* $\text{cond}(a_c)$. Each conditional effect $C \triangleright E \in \text{cond}(a_c)$ is composed of two sets of literals: $C \in \mathcal{L}(F)$, the *condition*, and $E \in \mathcal{L}(F)$, the *effect*. An action a_c is applicable in a state s if $\rho(s, a_c)$ is true, and the result of applying action a_c in state s is $\theta(s, a_c) = \{s \setminus \neg \text{eff}_c(s, a) \cup \text{eff}_c(s, a)\}$ where $\text{eff}_c(s, a)$ are the *triggered effects* resulting from the action application (conditional effects whose conditions hold in s):

$$\text{eff}_c(s, a) = \bigcup_{C \triangleright E \in \text{cond}(a_c), C \subseteq s} E,$$

2.2 The observation model

Given a classical planning problem $P = \langle F, A, I, G \rangle$, a plan π and a trajectory $\tau(\pi, s_0)$, we define the *observation of the trajectory* as a sequence of partial states that results from observing the execution of π on I . Formally, $\mathcal{O}(\tau) = \langle s_0^o, s_1^o, \dots, s_m^o \rangle$ where $s_0^o = I$.

A *partial state* s_i^o , $0 < i < m$, is one in which $|s_i^o| < |F|$; i.e., a state in which at least a fluent of F is not observable. Note that this definition also comprises the case $|s_i^o| = 0$, when the state is fully unobservable. Whatever the sequence of observed states of $\mathcal{O}(\tau)$ is, it must be *consistent* with the sequence of states of $\tau(\pi, s_0)$, meaning that $\forall i, s_i^o \subseteq s_i$. In practice, the number of observed states m , ranges from 1 (the initial state, at least), to $|\pi| + 1$, and the observed intermediate states will comprise a number of fluents between $[1, |F|]$.

We are assuming then that there is a *bijective monotone mapping* between trajectories and observations [Ramírez and Geffner, 2009], thus also granting the inverse consistency relationship (the trajectory is a superset of the observation). Therefore, transiting between two consecutive observed states in $\mathcal{O}(\tau)$ may require the execution of more than a single action ($\theta(s_i^o, \langle a_1, \dots, a_k \rangle) = s_{i+1}^o$, where $k \geq 1$ is unknown but finite. In other words, having $\mathcal{O}(\tau)$ does not imply knowing the actual length of π .

Definition 1 (Explaining a $\mathcal{O}(\tau)$ observation) *Given a classical planning problem P and an observation $\mathcal{O}(\tau)$, a plan π explains $\mathcal{O}(\tau)$ (denoted $\pi \mapsto \mathcal{O}(\tau)$) iff π is a solution for P that is consistent with the state trajectory constraints imposed by the sequence of partial states $\mathcal{O}(\tau)$.*

If π is also optimal, we say that π is the *best explanation* for the input observation $\mathcal{O}(\tau)$.

3 Computing the least-commitment action model from observations

First, this section formalizes the notion of the *least-commitment* action model that is able to *explain* an observation. Next, the section describes our approach to compute such model.

3.1 The least-commitment action model

The task of computing the *least-commitment* action model from a sequence of state observations is defined as $\langle \Phi, \mathcal{O}(\tau) \rangle$:

- $\Phi = \langle F, A[\cdot] \rangle$ is a *classical planning frame* where the semantics of each action $a \in A[\cdot]$ is unknown; i.e. the corresponding $\langle \rho, \theta \rangle$ functions are undefined. We say that an *action model* \mathcal{M} is a definition of the $\langle \rho, \theta \rangle$ functions of every action in $A[\cdot]$.
- $\mathcal{O}(\tau)$ is a sequence of partial states that results from the partial observation of a trajectory $\tau(\pi, s_0)$ within the *classical planning frame* Φ .

Given a *classical planning frame* $\Phi = \langle F, A[\cdot] \rangle$ and a sequence of partial states $\mathcal{O}(\tau) = \langle s_0^o, s_1^o, \dots, s_m^o \rangle$, we can build the classical planning problem $P_{\mathcal{O}} = \langle F, A[\cdot], s_0^o, s_m^o \rangle$. A model \mathcal{M} *explains* a sequence of observations $\mathcal{O}(\tau)$ iff, when the $\langle \rho, \theta \rangle$ functions of the actions in $P_{\mathcal{O}}$ are given by \mathcal{M} , there exists a solution plan for $P_{\mathcal{O}}$ that *explains* $\mathcal{O}(\tau)$.

Definition 2 (The least-commitment action model) *Given a $\langle \Phi, \mathcal{O}(\tau) \rangle$ task (and let M be the set of action models that represents the full space of possible action models for the actions in $A[\cdot] \in \Phi$), the least-commitment action model is the largest subset of models $M^* \subseteq M$ such that every model $\mathcal{M} \in M^*$ explains the input observation.*

This work focuses on the particular task of computing the *least-commitment* action model when action models are specified as STRIPS action schemata.

3.2 The space of STRIPS action models

A STRIPS *action schema* ξ is defined by four lists: A list of *parameters* $\text{pars}(\xi)$, and three list of predicates (namely $\text{pre}(\xi)$, $\text{del}(\xi)$ and $\text{add}(\xi)$) that shape the kind of fluents

```
(:action stack
:parameters (?v1 ?v2)
:precondition (and (holding ?v1) (clear ?v2))
:effect (and (not (holding ?v1)) (not (clear ?v2))
             (clear ?v1) (handempty) (on ?v1 ?v2)))

(pre_holding_v1_stack) (pre_clear_v2_stack)
(eff_holding_v1_stack) (eff_clear_v2_stack)
(eff_clear_v1_stack) (eff_handempty_stack) (eff_on_v1_v2_stack)
```

Figure 1: PDDL encoding of the `stack(?v1, ?v2)` schema and our propositional representation for this same schema.

that can appear in the *preconditions*, *negative effects* and *positive effects* of the actions induced from that schema. Let be Ψ the set of *predicates* that shape the propositional state variables F , and a list of *parameters* $\text{pars}(\xi)$. The set of elements that can appear in $\text{pre}(\xi)$, $\text{del}(\xi)$ and $\text{add}(\xi)$ of the STRIPS action schema ξ is given by FOL interpretations of Ψ over the parameters $\text{pars}(\xi)$. We denote this set of FOL interpretations as $\mathcal{I}_{\Psi, \xi}$. For instance, in the *blocksworld* the $\mathcal{I}_{\Psi, \xi}$ set contain eleven elements for the `stack(v_1, v_2)` schemata, $\mathcal{I}_{\Psi, \text{stack}} = \{\text{handempty}, \text{holding}(v_1), \text{holding}(v_2), \text{clear}(v_1), \text{clear}(v_2), \text{ontable}(v_1), \text{ontable}(v_2), \text{on}(v_1, v_1), \text{on}(v_1, v_2), \text{on}(v_2, v_1), \text{on}(v_2, v_2)\}$.

Despite any element of $\mathcal{I}_{\Psi, \xi}$ can *a priori* appear in the $\text{pre}(\xi)$, $\text{del}(\xi)$ and $\text{add}(\xi)$ of schema ξ , the space of possible STRIPS schemata is bounded by constraints of three kinds:

1. *Syntactic constraints.* STRIPS constraints require $\text{del}(\xi) \subseteq \text{pre}(\xi)$, $\text{del}(\xi) \cap \text{add}(\xi) = \emptyset$ and $\text{pre}(\xi) \cap \text{add}(\xi) = \emptyset$. Considering exclusively these syntactic constraints, the size of the space of possible STRIPS schemata is given by $2^{2 \times |\mathcal{I}_{\Psi, \xi}|}$. *Typing constraints* are also of this kind [McDermott *et al.*, 1998].
2. *Domain-specific constraints.* One can introduce domain-specific knowledge to constrain further the space of possible schemata. For instance, in the *blocksworld* one can argue that $\text{on}(v_1, v_1)$ and $\text{on}(v_2, v_2)$ will not appear in the $\text{pre}(\xi)$, $\text{del}(\xi)$ and $\text{add}(\xi)$ lists of an action schema ξ because, in this specific domain, a block cannot be on top of itself. *State invariants* are also constraints of this kind [Fox and Long, 1998].
3. *Observation constraints.* An observations $\mathcal{O}(\tau)$ depicts *semantic knowledge* that constraints further the space of possible action schemata.

In this work we introduce a propositional encoding of the *preconditions*, *negative*, and *positive* effects of a STRIPS action schema ξ using only fluents of two kinds $\text{pre}_e\xi$ and $\text{eff}_e\xi$ (where $e \in \mathcal{I}_{\Psi, \xi}$). This encoding exploits the syntactic constraints of STRIPS so is more compact than the one previously proposed by Aineto *et al.* 2018. In more detail, if $\text{pre}_e\xi$ and $\text{eff}_e\xi$ holds it means that $e \in \mathcal{I}_{\Psi, \xi}$ is a negative effect in ξ while if $\text{pre}_e\xi$ does not hold but $\text{eff}_e\xi$ holds, it means that $e \in \mathcal{I}_{\Psi, \xi}$ is a positive effect in ξ . Figure 1 shows the PDDL encoding of the `stack(?v1, ?v2)` schema and our propositional representation for this same schema.

```

Figure 2: *Partially specified* STRIPS model that represents of a set of action models for the `stack (?v1, ?v2)` schema.

3.3 Partially specified STRIPS action models

A set of action models can be defined *explicitely*, by enumerating all the models that belong to the set or *implicitely*, by enumerating the constraints that must satisfy any model that belongs to the set. Inspired by the notion of *incomplete (annotated) model* [Sreedharan *et al.*, 2018], we introduce here *partially specified* STRIPS action models, a formalism for the *implicit* representation of a set of STRIPS schema.

We show now that extending to the *knowledge level* our propositional encoding of STRIPS action schemes, we can compactly represent a set of STRIPS schema. The extension defines, for each proposition $pre_e_ξ$, with two propositions $Kpre_e_ξ$ and $K¬pre_e_ξ$, meaning that is *known* that $e ∈ \mathcal{I}_{\Psi, \xi}$ is a precondition of ξ and that is *known* that $e ∈ \mathcal{I}_{\Psi, \xi}$ is not a precondition of ξ . Likewise for each $eff_e_ξ$ proposition we define these two, $Keff_e_ξ$ and $K¬eff_e_ξ$, meaning that is *known* that $e ∈ \mathcal{I}_{\Psi, \xi}$ is an effect of ξ and that is *known* that $e ∈ \mathcal{I}_{\Psi, \xi}$ is not an effect of ξ . With respect to this formalization, the *full space* of possible STRIPS schemas for ξ is compactly represented as $\bigcap_{e \in \mathcal{I}_{\Psi, \xi}} \neg Kpre_e_ξ \wedge \neg K¬pre_e_ξ \wedge \neg Keff_e_ξ \wedge \neg K¬eff_e_ξ$.

Figure 2 shows a *partially specified* STRIPS model that represents of a set of action models for the `stack (?v1, ?v2)` schema. This *partially specified* STRIPS model represents a set of 2^5 models since (1), the actual five effects of the action are *unknown*, (2) preconditions are known to appear as in the actual definition of the `stack (?v1, ?v2)` schema for the blockworld and (3), it is *known* that the preconditions and effects that are not part of the actual definition of the `stack (?v1, ?v2)` schema are not part of this *partially specified* STRIPS model.

3.4 Computing the least-commitment model via classical planning

Inspired by the *classical planning compilation* K_{s_0} for conformant planning [Palacios and Geffner, 2009], this section shows that we can build a *classical planning problem* $P = \langle F', A', I', G' \rangle$ whose solution induces the *least-commitment* action model for an observation $\mathcal{O}(\tau)$:

- The set of fluents F' extends F with two new sets of fluents:
 - $\{test_j\}_{1 \leq j \leq m}$, indicating the state observation $s_j \in \mathcal{O}(\tau)$ where the action model is validated
 - The *knowledge level* fluents $Kpre_e_ξ$, $K¬pre_e_ξ$, $Keff_e_ξ$ and $K¬eff_e_ξ$ encoding the space of possible *partially specified* action models.

- The set of actions A' contains now actions of three different kinds:

- Actions for *committing* $pre_e_ξ$ to a positive/negative value. Similar actions are also defined for *committing* $eff_e_ξ$ to a positive/negative value but the value of $eff_e_ξ$ can only be committed once the value of the corresponding $pre_e_ξ$ is committed (i.e. once either $Kpre_e_ξ$ or $K¬pre_e_ξ$ holds in the current state).

$$\begin{aligned} pre(commit\top_pre_e_ξ) &= \{mode_{commit}, \\ &\quad \neg Kpre_e_ξ, \neg K¬pre_e_ξ\}, \\ cond(commit\top_pre_e_ξ) &= \{\emptyset\} \triangleright \{Kpre_e_ξ\}. \end{aligned}$$

$$\begin{aligned} pre(commit\bot_pre_e_ξ) &= \{mode_{commit}, \\ &\quad \neg Kpre_e_ξ, \neg K¬pre_e_ξ\}, \\ cond(commit\bot_pre_e_ξ) &= \{\emptyset\} \triangleright \{K¬pre_e_ξ\}. \end{aligned}$$

- Actions for *validating* that committed models explain the s_j observed states, $0 \leq j < m$.

$$\begin{aligned} pre(validate_j) &= s_j \cup \{test_{j-1}\}, \\ cond(validate_j) &= \{\emptyset\} \triangleright \{\neg test_{j-1}, test_j\}, \\ &\quad \{mode_{commit}\} \triangleright \{\neg mode_{commit}, mode_{val}\}. \end{aligned}$$

- *Editable* actions whose semantics is given by the value of the *knowledge level* fluents ($Kpre_e_ξ$, $K¬pre_e_ξ$, $Keff_e_ξ$ and $K¬eff_e_ξ$) at the current state. Figure 3 shows the PDDL encoding of an *editable* `stack (?v1, ?v2)` schema. This editable schema behaves exactly as the original PDDL schema defined in Figure 1 when the set of fluents $(Kpre_holding_v1_stack) (Kpre_clear_v2_stack) (Keff_holding_v1_stack) (Keff_clear_v2_stack) (Keff_clear_v1_stack) (Keff_handempty_stack) (Keff_on_v1_v2_stack)$ hold at the current state as well as the remaining $K¬pre_e_ξ$ and $K¬eff_e_ξ$ for all the preconditions and effects that are not part of the actual `stack (?v1, ?v2)` schema. Formally, given an operator schema $\xi \in \mathcal{M}$ its *editable* version is:

$$\begin{aligned} pre(editable_\xi) &= \{\neg K¬pre_e_ξ \implies e\}_{\forall e \in \mathcal{I}_{\Psi, \xi}} \\ cond(editable_\xi) &= \{Kpre_e_ξ, \neg K¬eff_e_ξ\} \triangleright \{\neg e\}_{\forall e \in \mathcal{I}_{\Psi, \xi}}, \\ &\quad \{K¬pre_e_ξ, \neg K¬eff_e_ξ\} \triangleright \{e\}_{\forall e \in \mathcal{I}_{\Psi, \xi}}. \end{aligned}$$

- The new initial state $I' = I \cup \{mode_{commit}\}$ while the new goals are $G' = s_m \cup \{test_m\}$.
